**MULTIPLE-SOURCE ARRAYS FOR CONFOCAL
AND NEAR-FIELD MICROSCOPY**

CROSS-REFERENCE TO RELATED APPLICATIONS

5 This application claims priority from provisional application Serial No.
60/221,019 filed July 27, 2000 by Henry A. Hill entitled "Multiple-Source Arrays for
Confocal and Near-Field Microscopy," the contents of which is incorporated herein by
reference.

10 BACKGROUND OF THE INVENTION

The invention relates to a class of novel mask structures that can provide
utilitarian improvements to the speed, signal-to-noise ratio and measurement bandwidth
of scanning microscopy.

Scanning microscopy techniques, including near-field and confocal scanning
15 microscopy, conventionally employ a single spatially localized detection or excitation
element, sometimes known as the scanning probe. The near-field scanning probe is
typically a sub-wavelength aperture positioned in close proximity to a sample; in this
way, sub-wavelength spatial resolution in the object-plane is obtained. The confocal
scanning probe employs diffraction-limited optics to achieve resolution of the order of
20 the optical wavelength. Spatially extended images are acquired by driving the scanning
probe in a raster pattern. Near-field microscopy conventionally produces two-
dimensional images in this manner. Confocal microscopy has the additional capability of
imaging volumes by extending the raster scan into a third dimension, depth.

Near-field and confocal scanning microscopy instruments typically achieve high spatial
25 resolution via the use of a single effective aperture to select a small area or volume of the
object plane or object. Unfortunately, transmission through the aperture is typically
small, thereby taxing optical detection hardware and often requiring long measurement
integration times.

30 SUMMARY OF THE INVENTION

The present invention features a class of novel mask structures applicable to
techniques broadly known as scanning microscopy. For example, embodiments provide

for a plurality of arrangements of a plurality of apertures with high optical throughput, with the capacity to effect utilitarian improvements to the speed, signal-to-noise ratio and measurement bandwidth. Such embodiments may be incorporated into microscopy systems designed to investigate the profile of a sample, to read optical data from a sample, and/or write optical data to a sample.

In general, in one aspect, the invention features a multiple-source array for illuminating an object. The multiple source array includes: a source of electromagnetic radiation having a wavelength λ in vacuum; and a reflective mask positioned to receive the electromagnetic radiation. The reflective mask includes an array of spatially separated apertures. Each aperture includes a dielectric material defining a waveguide having transverse dimensions sufficient to support one or more guided propagating modes of the electromagnetic radiation extending through the mask. Furthermore each aperture configured to radiate a portion of the electromagnetic radiation to the object.

Embodiments of the multiple source array may include any of the following features.

The reflective mask may further include a reflective dielectric stack surrounding the array of apertures. For example, the reflective dielectric stack may include alternating layers of different dielectric materials. The refractive indices of the dielectric materials in the alternating layers may be smaller than the refractive index of the dielectric material in each aperture. The reflective mask may further include a reflective/absorbing layer (e.g., a metal layer) positioned to attenuate evanescent components of the guided propagating modes extending away from the apertures. The reflective/absorbing layer typically has a thickness greater than the skin depth of the electromagnetic radiation for the reflective/absorbing layer material. The reflective/absorbing layer may be positioned on one side of the dielectric stack. Alternatively, the reflective mask may further include a dielectric screening layer, and the reflective/absorbing layer is positioned between the dielectric screening layer and the dielectric stack. Furthermore, the reflective/absorbing layer may be formed by a series of pads in a common plane, wherein adjacent pads are spaced from one another by an amount sufficient to suppress plasmon oscillations in the reflective/absorbing layer.

The mask may further include an end mask portion positioned adjacent the object.

Each aperture further includes a secondary aperture formed in the end mask portion and aligned with the corresponding waveguide. Each secondary aperture has a transverse dimension smaller than the transverse dimensions of the corresponding waveguide.

Furthermore, the transverse dimension of each secondary aperture may be smaller than the vacuum wavelength of the electromagnetic radiation provided by the source. In addition, the mask may further include a reflective dielectric stack surrounding each of the waveguides. The end mask portion may include a metal layer. Also, each waveguide may define an optical cavity between opposite sides of the mask, and wherein the length of each waveguide is selected to cause the optical cavity to be resonant with the electromagnetic radiation.

The reflective mask may further includes an antireflection coating positioned adjacent the object.

At least some of the apertures may be substantially cylindrical and the cylindrical apertures may have a diameter on the order of $\lambda/2n_3$, where n_3 is the refractive index of the dielectric material in each corresponding aperture.

At least one of the transverse dimensions of each aperture may be on the order of $\lambda/2n_3$, where n_3 is the refractive index of the dielectric material in each corresponding aperture. Furthermore, another of the transverse dimensions of at least one of the apertures is smaller than $\lambda/2n_3$.

At least some of the apertures in the reflecting mask may define a periodic array. For example, the periodic array may include a multi-aperture basis.

The apertures may include a first set of apertures having properties sufficient to support a first set of one or more guided propagating modes of the electromagnetic radiation extending through the mask and a second set of apertures having properties sufficient to support a second set of one or more guided propagating modes of the electromagnetic radiation extending through the mask, wherein the first set of one or more guided propagating modes differs from the second set of one or more guided propagating modes. For example, the first set of apertures may define a first periodic array of apertures and the second set of apertures may define a second period array of apertures.

The dielectric material in at least one of the apertures may be silicon.

The wavelength λ provided by the source may be an optical wavelength.

The source may direct the electromagnetic radiation to contact the reflective mask at an angle with respect to a normal axis for the mask.

5 The source may direct the electromagnetic radiation to contact the reflective mask as a standing wave pattern.

The multiple source array may further include an optical substrate attached to the reflective mask, wherein the optical substrate is substantially transparent to the electromagnetic radiation. For example, the optical substrate may provide mechanical
10 stability to the reflective mask. Furthermore, the optical substrate may include a curved surface to provide light gathering or focusing.

The multiple source array may further include a uniform dielectric layer formed over the reflective mask, wherein the dielectric material in the apertures and the dielectric layer formed over the mask include a common dielectric material. Furthermore, there
15 may be an anti-reflection coating formed over the uniform dielectric layer.

In general, in another aspect, the invention features a multiple-source array for illuminating an object with electromagnetic radiation having a wavelength λ in vacuum. The multiple-source array includes a reflective mask including an array of spatially separated apertures. Each aperture includes a dielectric material defining a waveguide
20 having transverse dimensions sufficient to support one or more guided propagating modes of the electromagnetic radiation extending through the mask. Furthermore, each aperture is configured to radiate a portion of the electromagnetic radiation to the object. Feature of the multiple-source array may include any of those described above.

In general, in another aspect, the invention features a method for illuminating an
25 object with electromagnetic radiation having a wavelength λ in vacuum. The method including: providing a mask including an array of waveguides; and coupling a portion of the electromagnetic radiation through each waveguide to illuminate different spatial regions of the object. The method may further include features corresponding to any of those described above in connection with the multiple-source arrays.

30 Any of the embodiments may be incorporated into the confocal and near-field confocal, microscopy systems described in the following, commonly owned provisional

utility

applications: Serial No. 09/631,230 filed August 2, 2000 by Henry A. Hill entitled

Field Microscopy" and the corresponding Utility Application Serial No. _____

having the same title filed on July 27, 2001; the contents of each of the preceding
applications being incorporated herein by reference. Aspects and features disclosed in
the preceding provisional applications may be incorporated into the embodiments

20 described in the present application.

Embodiments of the invention may include any of the following advantages.

One advantage is sub-wavelength spatial resolution in the object-plane, measured
with respect to the vacuum-wavelength of an operating light source.

25 Another advantage is the use of a dielectric stack to provide a highly reflective
mask surrounding the apertures. As a result, the reflective mask may used as one of
multiple optics forming an optical cavity used to enhance the radiation energy on one side
of the mask. In turn, the aperture waveguide couples radiation from the optical cavity to
the opposite side of dielectric stack.

30 Another advantage is the ability to achieve high optical throughput for object-
plane resolutions comparable to the resolution of conventional near-field microscopy.

Another advantage is an aperture array with the capability to acquire many image points simultaneously for high data-rate end-uses.

Another advantage is the capacity to bring many nominally identical scanning probes into uniformly controlled proximity to an object-plane.

5 Another advantage is a high degree of immunity to external mechanical disturbances.

Another advantage is the use of multiple near-field mode-structures not directly utilized by conventional near-field microscopy.

10 Another advantage is the ability to combine multiple types of scanning probes, each possessing properties tailored for a particular end-use, on a single platform in a planar geometry.

Another advantage is the integration of the aperture array with a supporting optical substrate which may be further figured to provide optical focusing or collection functions.

15 Another advantage is a method to further improve spatial resolution with the use of one or more absorbing or reflecting interlayer masks.

Another advantage is a method to suppress spurious or undesired interactions between the aperture array and materials in or near the object plane.

20 Another advantage is a method to suppress plasmon effects affecting certain aperture arrays.

Another advantage is operation in a traveling-wave-excitation modality for simultaneous optical transmission through an array of apertures.

Another advantage is operation in a phased-array modality.

25 Another advantage is operation in a mode-matched standing-wave-excitation modality for enhanced optical throughput through an array of simultaneously excited apertures.

Another advantage is the variable and selective excitation of periodic subsets of apertures in a standing-wave-excitation modality by tuning the periodicity of a standing wave pattern.

Another advantage is the variable and selective excitation of periodic subsets of apertures in a standing-wave-excitation modality by spatial rotation of a standing-wave pattern.

Another advantage is the combination of two or more aperture arrays variably and selectively excitable in a traveling-wave or standing-wave modality incorporating any of the fifteenth or sixteenth advantages.

Another advantage is the capacity to integrate anti-reflection and mode-matching structures directly into the aperture arrays to effect optimal transmission efficiency of the aperture arrays.

For convenience, the embodiments that follow are described with reference to electromagnetic radiation at optical wavelengths. Further embodiments at other wavelengths are also within the scope of the invention.

Other features, aspects, and advantages follow.

BRIEF DESCRIPTION OF THE DRAWINGS

In the drawings, wherein like reference characters denote similar elements throughout the several views:

FIG. 1A, FIG. 1B, FIG. 1C, FIG. 1D and FIG. 1E illustrate, in schematic form, the presently preferred first embodiment of the instant invention, including a general conception of dielectric apertures (**FIG. 1A**) arranged on a two-dimensional lattice and the non-limiting example of circular dielectric apertures arranged on a two-dimensional lattice (**FIG. 1B**), each incorporated into an otherwise highly reflective planar mask; one-dimensional arrays (**FIG. 1C and FIG. 1D**) are shown to be a special case of two-dimensional arrays; arbitrary arrangements of dielectric apertures (**FIG. 1E**) are shown to be special cases of one-dimensional or two-dimensional arrays;

FIG. 2 illustrates, in schematic form, the construction of a typical dielectric aperture in an otherwise highly reflective planar mask and as such illustrates several aspects of the presently preferred first embodiment;

FIG. 3A, FIG. 3B and FIG. 3C illustrate, in schematic form, three fabrication methods which may be employed to effect in part the realization of the instant invention;

FIG. 4 illustrates, in schematic form, the presently preferred second embodiment of the instant invention, comprising a generalization of the presently preferred first embodiment to include multiple kinds of circular dielectric apertures forming a basis to be repeated on a lattice;

FIG. 5 illustrates, in schematic form, the presently preferred third embodiment of the instant invention, including rectangular dielectric apertures arranged on a lattice;

FIG. 6 illustrates, in schematic form, the presently preferred fourth embodiment of the instant invention, comprising a generalization of the presently preferred third embodiment to include multiple kinds of rectangular dielectric apertures forming a basis to be repeated on a lattice;

FIG. 7 illustrates, in schematic form, the presently preferred fifth embodiment of the instant invention, comprising a generalization of the presently preferred second and fourth embodiments to include multiple kinds of dielectric apertures including circular dielectric apertures and rectangular dielectric apertures forming a basis to be repeated on a lattice;

FIG. 8A and **FIG. 8B** illustrate, in schematic form, the presently preferred sixth embodiment of the instant invention, incorporating the presently preferred first through fifth embodiments, inclusive, and an absorbing or reflecting interlayer to improve spatial resolution with minimized interaction between the aperture array and materials in or near the object plane;

FIG. 9A and **FIG. 9B** illustrate, in schematic form, the presently preferred seventh embodiment of the instant invention, an adaptation of the presently preferred sixth embodiment to reduce coupling between members of the aperture array;

FIG. 10A and **FIG. 10B** illustrate, in schematic form, the presently preferred eighth embodiment of the instant invention, describing the combination of any of presently preferred first through seventh embodiments, inclusive, with an optical substrate;

FIG. 11 illustrates, in schematic form, the presently preferred ninth embodiment {KBF} of the instant invention, describing operation of the presently preferred eighth embodiment with a traveling wave to produce optical fields on the output side of an aperture array, including options to produce phased array outputs;

FIG. 12 illustrates, in schematic form, the presently preferred tenth embodiment of the instant invention, describing operation of the presently preferred eighth embodiment with a standing wave to produce enhanced optical fields on the output side of an aperture array, including options to selectively excite subsets of the aperture array;

FIG. 13 illustrates, in schematic form, the presently preferred eleventh embodiment of the instant invention, an adaptation of the presently preferred tenth embodiment to include multiple aperture arrays on a single otherwise highly reflecting mask;

FIG. 14A and **FIG. 14B** illustrate, in schematic form, the presently preferred twelfth embodiment of the instant invention, an adaptation of the presently preferred sixth embodiment of simplified design and construction; and

FIG. 15 illustrates, in schematic form, the presently preferred thirteenth embodiment of the instant invention, an adaptation of presently preferred first through fourteenth embodiments, inclusive, including an integral anti-reflection structure and an integral mode-matching structure.

FIG. 16A and **FIG. 16B** illustrate, in schematic form, additional embodiments of the invention in which an end mask portion provides at least one secondary aperture to further increase the spatial resolution of the source array.

DETAILED DESCRIPTION OF THE INVENTION

Referring to the drawings in detail, **FIG. 1A** and **FIG. 1B** illustrate, in schematic form, the presently preferred first embodiment of the instant invention. Aperture array mask generally indicated as **100** comprises an highly reflective planar dielectric multilayer stack **101** of thickness d with embedded cylindrical dielectrics **111** of arbitrary cross-sections shown in **FIG. 1A**. The essential feature of embedded cylindrical dielectrics **111** is that each of embedded cylindrical dielectrics **111** supports at least one guided optical mode propagating in a direction perpendicular to the surface of stack **101**. A non-limiting example is illustrated in **FIG. 1B** by circularly cylindrical dielectrics **102** of diameter D arranged in a two-dimensional array.

The array is represented as a simple finite square lattice in **FIG. 1B**, but it is understood that the array may possess any periodic structure in one or two dimensions. A non-limiting example of a one-dimensional array is illustrated in **FIG. 1C** wherein

cylindrical dielectrics **102** are embedded in multilayer stack **101** at relative positions given by finite repetition of a simple lattice of lattice-vector \vec{a} . Another non-limiting example of a one-dimensional array is illustrated in **FIG. 1D**: a basis comprising three dielectric cylinders **102A**, **102B** and **102C** is replicated at positions given by finite repetition of lattice-vector \vec{a} .

Two-dimensional arrays are formed by generalizations of one-dimensional arrays. Two-dimensional arrays are described by analogy to well-known principles of crystalline structure. A two-dimensional lattice in the plane of the mask generally indicated as **100** is therefore defined by any pair of non-collinear vectors, \vec{a} and \vec{b} , each of which has nonzero length and is parallel to the surface of the mask generally indicated as **100**. The lattice may possess either a simple one-element basis as shown in **FIG. 1B** or a basis comprising multiple dielectric cylinders of type **102** without departing from the spirit of the instant invention. The lateral extent of the array may also be larger or smaller than the 5x5 array of **FIG. 1B** without departing from the spirit of the instant invention. Specifically, a finite lattice of dimension $\{M \times N\}$ is formed by repeating a basis comprising one or more dielectric cylinders **102** at all locations $m\vec{a} + n\vec{b}$ for m chosen from the set of the first M natural numbers, $\{1, 2, \dots, M\}$ and n chosen from the set of the first N natural numbers, $\{1, 2, \dots, N\}$. All one-dimensional arrays are then understood to be special cases of two-dimensional arrays, $\{1 \times N\}$ or $\{M \times 1\}$ for N or M nonzero respectively.

The special case of an arbitrary arrangement of dielectric cylinders of arbitrary cross-sections and indices of refraction, a non-limiting example of which is illustrated in **FIG. 1E**, is clearly understood to be included in the general definition of a lattice with a basis, *supra*. Specifically, the special case of an array of dimension $\{1 \times 1\}$ comprises a single lattice point. Attaching to said lattice point a basis comprising an arbitrary number of dielectric cylinders of arbitrary cross-sections and arbitrary indices of refraction results in a utilitarian structure. Such an arrangement is illustrated in **FIG. 1E** with dielectric cylinders **103A**, **103B**, **103C**, **103D** and **103E**.

Referring to the drawings in detail, **FIG. 2** illustrates, in schematic form, a small section generally indicated as **200** of the mask generally indicated as **100** of the presently preferred first embodiment. The dielectric multilayer stack **201** comprises periodically

arranged layers of two or more dielectric materials chosen to produce a desired spectral reflectance characteristic, usually high reflectance over a defined “stop-band” of optical frequencies.

A simple stack of alternating layers **203** and **204** of refractive indices n_1 and n_2 , respectively, is shown in **FIG 2** to provide a non-limiting example of an highly reflective dielectric stack. It will be understood by those practiced in the art that other dielectric stacks are possible without departing from the spirit of the instant invention and that the scope of the instant invention includes all multilayer dielectric structures. The thickness d of the mask generally indicated as **200** is determined by the number and types of layers required to achieve a desired reflectance for a particular end-use and may be of the order of a micrometer for optical applications.

The refractive index $n_3 > \max\{n_1, n_2\}$ of dielectric circular cylinders **202** such that the resulting structure supports one or more guided electromagnetic modes propagating along the axis of dielectric circular cylinder **202**. The diameter D of dielectric circular cylinders **202** is therefore of the order of $\lambda/(2n_3)$ for an operating wavelength λ measured in vacuum.

We now provide a numerical example to illustrate the manner in which the instant invention derives high spatial resolution. If the operating wavelength is, for example, 633 nm and n_3 is, as for silicon, 3.88, then the lowest-order mode has a spatial extent of approximately 82 nm. The diameter D of dielectric circular cylinders **202** would be made at least 82 nm to support this mode. The resulting spatial resolution which results by coupling this mode to an object-plane in the near-field remains substantially higher than obtainable at the diffraction-limit of approximately $\lambda/2 \sim 316$ nm in air.

Moreover, an aperture of index of refraction n_3 and diameter of order of $\lambda/(2n_3)$ supports at least one guided (i.e., propagating) mode. An aperture of index of refraction n , with n less than n_3 , and diameter $\lambda/(2n_3)$ would, however, support no guided mode; such an aperture would have poor optical transmission and be said to be “cut-off.” The optical throughput of an aperture of diameter $\lambda/(2n_3)$ and filled with dielectric of index of refraction n_3 , is therefore greater than would be realized with an aperture of diameter $\lambda/(2n_3)$ filled with a dielectric of index of refraction less than n_3 , such as air or glass.

Thus, the optical throughput of the mask generally indicated as **200** is enhanced by using dielectric cylinders **202** of high index of refraction.

Moreover, the waveguiding structure of **FIG. 2** is readily replicated in well-defined arrays such as those of the mask generally indicated as **100** in **FIG. 1B**. The planar design of the mask generally indicated as **100** in **FIG. 1B** permits arbitrarily close approach of the mask generally indicated as **100** in **FIG. 1B** to an object plane.

Moreover, the fixed spatial relationship between dielectric circular cylinders **102** of **FIG. 1B** provides an important degree of immunity to external mechanical perturbations, even for imperfectly fabricated instances of the mask generally indicated as **100** in **FIG. 1B**.

A further refinement, implicit in the description of the presently preferred first embodiment, is the capacity to employ one or more higher-order transverse modes of the waveguiding structure of **FIG. 2**, provided the diameter D of dielectric circular cylinders **202** of **FIG. 2** is made sufficiently large to permit efficient transmission at the desired operating wavelength(s), to the extent and degree that different transverse modes interact in measurably distinct fashions with features in an object plane.

Referring to the drawings in detail, **FIG. 3A** and **FIG. 3B** illustrate, in schematic form, four non-exclusive, non-limiting nano-machining methods by which aperture array masks generally indicated as **100** of the presently preferred first embodiment may be fabricated. The methods of **FIG. 3A** and **FIG. 3B** each involve etching high-aspect-ratio pedestals in, for example, a silicon substrate. The nano-machining may be accomplished by any of several established processes, such as those disclosed in U.S. Patent No. 5,198,390 and documents cited therein. The resulting pedestals form the dielectric cylinders **102** of the presently preferred first embodiment. The dielectric multilayer stack **101** of the presently preferred first embodiment is then evaporated over the pedestals either directly, as in **FIG. 3A**, or after a layer of selectively exposed photoresist, as in **FIG. 3B**.

The direct-evaporation method of **FIG. 3A** requires a planarizing operation, such as chemical-mechanical polishing, to produce the final structure.

The lift-off method of **FIG. 3B** uses the same mask as the nano-machining step to expose a layer of resist. The unexposed resist is washed away before evaporating the

dielectric multilayer stack **101** of the presently preferred first embodiment. Finally, the exposed resist is lifted off to form the final structure.

The method of **FIG. 3C** involves milling openings in dielectric multilayer stack **101** of the presently preferred first embodiment by the same or similar nano-machining methods used in **FIG. 3A** and **FIG. 3B**. The resulting voids are then backfilled, as for instance by a process such as that disclosed in U.S. Patent No. 6,030,881 and documents cited therein, with a material of high dielectric constant, such as silicon or silicon nitride. Finally, the excess backfill material is removed by a planarizing operation, such as chemical-mechanical polishing, to produce the final structure.

Referring to the drawings in detail, **FIG. 4** illustrates, in schematic form, the presently preferred second embodiment of the instant invention. The mask generally indicated as **400** comprises an highly reflective planar dielectric multilayer stack **401** substantially similar to multilayer stack **101** of the presently preferred first embodiment with embedded circularly cylindrical dielectrics **402A** and **402B** of diameters D_A and D_B and refractive indices n_{3A} and $n_{3B} > \max\{n_1, n_2\}$, respectively, arranged as a square lattice with a basis. The basis in **FIG. 4** comprises one each of dielectric circular cylinders of types **402A** and **402B**. The general properties of dielectric circular cylinders **402A** and **402B** are similar to those of dielectric circular cylinders **102** of the presently preferred first embodiment, and the discussion of dielectric circular cylinders **102** of the presently preferred first embodiment applies to each of dielectric circular cylinders **402A** and **402B**.

Thus, the guided modes of dielectric circular cylinders **402A** and **402B** can be fabricated to provide discernable spatial resolutions.

The lateral extent of the array may also be larger or smaller than the 5x5 array of **FIG. 4** without departing from the spirit of the instant invention. The basis may be made more or less complex than the two-element basis of **FIG. 4** without departing from the spirit of the instant invention. Moreover it is understood that the basis may comprise more than two types of dielectric circular cylinders, as for example in support of the seventh advantage, without departing from the spirit of the instant invention.

That the presently preferred fourth embodiment also supports the first through sixth advantages, inclusive, is clear from the foregoing exposition.

Referring to the drawings in detail, **FIG. 5** illustrates, in schematic form, the presently preferred third embodiment of the instant invention. The mask generally indicated as **500** comprises an highly reflective planar dielectric multilayer stack **501** substantially similar to multilayer stack **101** of the presently preferred first embodiment with embedded rectangular cylindrical dielectrics **502** of edge dimensions a and b and refractive index $n_3 > \max\{n_1, n_2\}$.

The resulting rectangular waveguiding structure serves purposes substantially similar to those of dielectric circular cylinders **102** of the presently preferred first embodiment, with one essential exception. Unlike dielectric circular cylinders **102** of the presently preferred first embodiment, which for given indices n_1 , n_2 and n_3 support guided propagating modes characterized by a desired operating optical frequency only for diameters larger than a critical "cut-off" diameter, rectangular cylindrical waveguide **502** supports at least one guided propagating mode as either dimension a or b , but not both, is made arbitrarily small. Under these conditions, the smaller of dimensions a or b defines the one-dimensional spatial resolution of the scanning probe. Consequently, high optical throughput can be achieved by maintaining the larger of dimensions a or b comparable to or larger than $\lambda/(2n_3)$.

A further refinement, implicit in the description of the presently preferred third embodiment, is the capacity to excite one or more higher-order transverse modes of the waveguiding structure of **FIG. 5** in support of the sixth advantage, to the extent and degree that different transverse modes interact in identifiably distinct and measurable fashions with features in an object plane. This can be accomplished by providing that at least one of dimensions a or b is made sufficiently large to permit efficient transmission at the desired operating wavelength(s).

The lateral extent of the array may also be larger or smaller than the 2x2 array of **FIG. 5** without departing from the spirit of the instant invention.

The basis may be made more or less complex than the one-element basis of **FIG. 5** without departing from the spirit of the instant invention.

It is evident that the presently preferred third embodiment also supports the third through fifth advantages, inclusive, in the manner of the presently preferred first embodiment.

Referring to the drawings in detail, **FIG. 6** illustrates, in schematic form, the presently preferred fourth embodiment of the instant invention. Mask **600** comprises an highly reflective planar dielectric multilayer stack **601** substantially similar to multilayer stack **101** of the presently preferred first embodiment with embedded dielectric rectangular cylinders **602A** and **602B** of edge dimensions $a_A \times b_A$ and $a_B \times b_B$ and refractive indices n_{3A} and $n_{3B} > \max\{n_1, n_2\}$, respectively, arranged as a square lattice with a basis. The general properties of dielectric rectangular cylinders **602A** and **602B** are similar to those of dielectric rectangular cylinders **502** of the presently preferred third embodiment and the discussion of dielectric rectangular cylinder **502** of the presently preferred third embodiment applied to each of dielectric rectangular cylinders **602A** and **602B**.

Thus, the guided modes of dielectric rectangular cylinders **602A** and **602B** can be fabricated to provide discernable spatial resolutions. For example, dielectric cylinders **602A** and **602B** may be fabricated with different sizes and/or orientations, to effect sensitivity to different spatial resolutions in a single aperture array.

The lateral extent of the array may also be larger or smaller than the 2x2 array of **FIG. 6** without departing from the spirit of the instant invention.

The basis may be made more or less complex than the two-element basis of **FIG. 6** without departing from the spirit of the instant invention. Moreover it is understood that the basis may comprise more than two types of dielectric rectangular cylinders, as for example in support of the seventh advantage, without departing from the spirit of the instant invention.

That the presently preferred fourth embodiment also supports the first through sixth advantages, inclusive, is obvious from the foregoing exposition.

Referring to the drawings in detail, **FIG. 7** illustrates, in schematic form, the presently preferred fifth embodiment of the instant invention. The mask generally indicated as **700** comprises an highly reflective planar dielectric multilayer stack **701** substantially similar to multilayer stack **101** of the presently preferred first embodiment with embedded dielectric cylinders **702A**, **702B**, and **702C** forming a three-element basis arranged on a 2x2 square lattice. Rectangular dielectric cylinders **702A** and **702B** have dimensions $a_A \times b_A$ and $a_B \times b_B$ and refractive indices n_{3A} and $n_{3B} > \max\{n_1, n_2\}$,

respectively. Dielectric circular cylinder **702C** has diameter D_C and refractive index n_{3C}
' > $\max\{n_1, n_2\}$.

Thus, the guided modes of dielectric cylinders **702A**, **702B** and **702C** can be
fabricated to provide discernable spatial resolutions.

5 The relative orientations of dielectric cylinders **702A** and **702B** inform a non-limiting
example by which the description of a dielectric cylinder not possessing complete two-
dimensional rotational symmetry includes specification of the orientation of said
dielectric cylinder.

The lateral extent of the array may also be larger or smaller than the 2x2 array of
10 **FIG. 7** without departing from the spirit of the instant invention.

The basis may be made more or less complex than the three-element basis of **FIG. 7**
without departing from the spirit of the instant invention.

Moreover it is understood that the basis may comprise more or fewer than three types
of dielectric rectangular cylinders, as for example in support of the seventh advantage,
15 without departing from the spirit of the instant invention.

That the presently preferred fourth embodiment also supports the sixth through sixth
advantages, inclusive, is obvious from the foregoing exposition.

Referring to the drawings in detail, **FIG. 8A** and **FIG. 8B** illustrate, in schematic
form, the presently preferred sixth embodiment of the instant invention. The mask
generally indicated as **800** comprises an highly reflective planar dielectric multilayer
stack **801** substantially similar to multilayer stack **101** of the presently preferred first
embodiment, with embedded dielectric cylinders **802**, save for the addition of an
20 absorbing or reflecting interlayer **805**.

It is understood that the type and arrangement of dielectric cylinders **802** is not
25 limited to the geometry of **FIG. 8A** and may be any instance described by any of the
several preferred embodiments documented herein.

Absorbing or reflecting interlayer **805** may lie above or below any dielectric layer
803 or **804** and is advantageously placed on that mask surface which will be placed
nearest the object-plane, as shown in **FIG. 8A**, where absorbing or reflecting interlayer
30 **805** serves to improve the effective resolution of the aperture array by attenuating the
evanescent component(s) of the guided mode(s) of a dielectric cylinder **802**. Specifically,

by attenuating evanescent component(s), the effective spatial resolution in the near-field of the aperture is defined chiefly by the geometry of the aperture rather than the spatial extent of the evanescent component(s). The thickness of absorbing or reflecting interlayer **805** is therefore of the order of one or more times the skin-depth of light of the operating wavelength in the absorbing or reflecting interlayer. A non-limiting example of an absorbing or reflecting interlayer is a metal.

Absorbing or reflecting interlayer **805** may also be advantageously placed between dielectric layers near that mask surface which will be placed nearest the object-plane, as shown in **FIG. 8B**, where absorbing or reflecting interlayer **805** serves to improve the effective resolution of the aperture array by attenuating the evanescent component(s) of the guided mode(s) of a dielectric cylinder **802**. Specifically, by attenuating evanescent component(s), the effective spatial resolution in the near-field of the aperture is defined chiefly by the geometry of the aperture rather than the spatial extent of the evanescent component(s). The embodiment of **FIG. 8B** is therefore advantageous over the embodiment of **FIG. 8A** inasmuch as the potential for interaction between the absorbing or reflecting interlayer and materials in or near the object-plane is reduced, in direct support of the tenth advantage. This is achieved by “burying” the absorbing or reflecting interlayer **805** behind a screening dielectric **806**, which may or may not be identical to either dielectric layer **803** or **804**. The criteria for choosing the dimensions of absorbing or reflecting interlayer **805** are the same for the embodiment of **FIG. 8B** as for the embodiment of **FIG. 8A**.

Referring to the drawings in detail, **FIG. 9A** and **FIG. 9B** illustrate, in schematic form, the presently preferred seventh embodiment of the instant invention. The mask generally indicated as **900** comprises an highly reflective planar dielectric multilayer stack **901** substantially similar to multilayer stack **101** of the presently preferred first embodiment, with embedded dielectric cylinders **902**, save for the addition of an absorbing or reflecting interlayer pads **905**. It is understood that the type and arrangement of dielectric cylinders **902** is not limited to the geometry of **FIG. 9A** and may be any instance described by any of the several preferred embodiments documented herein.

Absorbing or reflecting interlayer pads **905** may lie above or below any dielectric layer **903** or **904** and are advantageously placed on that mask surface which will be placed nearest the object-plane, as shown in **FIG. 9A**, where absorbing or reflecting interlayer pads **905** serve to improve the effective resolution of the aperture array by attenuating the evanescent component(s) of the guided mode(s) of a dielectric cylinder **902**. Specifically, by attenuating evanescent component(s), the effective spatial resolution in the near-field of the aperture is defined chiefly by the geometry of the aperture rather than the spatial extent of the evanescent component(s). The thickness of absorbing or reflecting interlayer pads **905** is therefore of the order of one or more times the skin-depth of light of the operating wavelength in the absorbing or reflecting interlayer. A non-limiting example of an absorbing or reflecting interlayer pad is a metal. The lateral extent s of the absorbing or reflecting interlayer pads **905** is of the order of the characteristic lateral extent of the evanescent component(s) of the guided mode(s). The minimum separation g between the perimeters of any two absorbing or reflecting interlayer pads **905** is chosen sufficient to electronically decouple all absorbing or reflecting interlayer pads **905**. Specifically, the separation g can be chosen sufficient to suppress plasmon oscillations involving any two or more absorbing or reflecting interlayer pads **905**.

Absorbing or reflecting interlayer pads **905** may also be advantageously placed between dielectric layers **903** and **904** near that mask surface which will be placed nearest the object-plane, as shown in **FIG. 9B**, where absorbing or reflecting interlayer pads **905** serve to improve the effective resolution of the aperture array by attenuating the evanescent component(s) of the guided mode(s) of a dielectric cylinder **902**, as described in the preceding paragraph and **FIG. 9A**. The embodiment of **FIG. 9B** is advantageous over the embodiment of **FIG. 9A** inasmuch as the potential for interaction between the absorbing or reflecting interlayer and materials in or near the object-plane is reduced in support of the tenth advantage. This is achieved by “burying” the absorbing or reflecting interlayer **905** behind a screening dielectric **906**, which may or may not be identical to either dielectric layer **903** or **904**. The criteria for choosing the dimensions and separations of absorbing or reflecting interlayer pads **905** are the same for the embodiment of **FIG. 9B** as for the embodiment of **FIG. 9A**.

Referring to the drawings in detail, **FIG. 10A** and **FIG. 10B** illustrate, in schematic form, the presently preferred eighth embodiment of the instant invention. Aperture array **1001** is of any of the types described by the preferred embodiments first through seventh documented herein and is fabricated directly on a flat optical substrate **1002** in **FIG. 10A**.

5 Aperture array **1001** is fabricated directly on an optical substrate **1002** in **FIG. 10A**. Optical substrate **1003** of **FIG. 10B** is figured to implement light-gathering or focusing as required for particular end-uses, in support of the eighth advantage. Both types optical substrates **1002** and **1003** provide a mechanically stable platform for fabrication and mounting of aperture array **1001**.

10 Referring to the drawings in detail, **FIG. 11** illustrates, in schematic form, the presently preferred ninth embodiment of the instant invention. Aperture array mask **1101** is fabricated or otherwise mounted on optical substrate **1103** described in the presently preferred eighth embodiment. Aperture array **1101** is illuminated through optical substrate **1103** by a traveling wave **1104** described by principal wavevector \vec{k} making an angle of incidence θ between \vec{k} and surface-normal \vec{n} and an angle ϕ between a fixed but arbitrary vector \vec{X} perpendicular to surface normal \vec{n} and the projection \vec{k}_{\parallel} of \vec{k} on a plane parallel to \vec{X} . The apertures **1102** of aperture array mask **1101** so illuminated are simultaneously excited to the extent that the traveling wave mode profile is congruent with the mode(s) guided by the individual apertures **1102**. The apertures **1102** are thereby illuminated with systematically varying phases for any angle θ not equal to zero. The character of the resulting transmission of light from the apertures **1102** is well known to those practiced in the art as a “phased array” with utility also well known to those practiced in the art. Moreover, the orientation of this phased array may be rotated in a plane either by rotating mask **1101** and substrate **1102** together or by rotating \vec{k} about \vec{n} to effect a change in angle ϕ .

20
25

Referring to the drawings in detail, **FIG. 12** illustrates, in schematic form, the presently preferred tenth embodiment of the instant invention. Aperture array mask **1201** is fabricated or otherwise mounted on optical substrate **1203** as described in the presently preferred eighth embodiment.

Aperture array **1201** is illuminated through optical substrate **1203** by a standing-wave intensity-pattern **1204** described by period and contours of equal amplitude making an angle $\pi/2-\phi$ between a fixed but arbitrary vector X perpendicular to surface normal \bar{n} . Standing-wave intensity-pattern **1204** may be produced by any of the interferometric or holographic methods well known to those practiced in the art. The apertures **1202** of aperture array mask **1201** so illuminated are simultaneously excited to the extent that the standing-wave mode-profile is congruent with the mode(s) guided by the individual apertures **1202**. The apertures **1202** are thereby excited to the extent that the antinodes of the standing-wave pattern overlap apertures **1202**.

Hence, the number and spacing of excited apertures may be controlled to purpose either (i) by rotating mask **1201** and substrate **1202** together in support of the sixteenth advantage or (ii) by rotating standing-wave pattern **1204** about \bar{n} to effect a change in angle ϕ in support of the sixteenth advantage or (iii) by changing the period of the standing-wave pattern.

Referring to the drawings in detail, **FIG. 13** illustrates, in schematic form, the presently preferred eleventh embodiment of the instant invention. Composite aperture array mask **1301** is fabricated or otherwise mounted on optical substrate **1303** described in the presently preferred eighth embodiment. Composite aperture array **1301** comprises two or more aperture arrays of types described in presently preferred first through seventh embodiments, each with independent lattice and basis specifications, combined in a single aperture array.

Aperture array **1301** is illuminated through optical substrate **1303** by a standing-wave intensity-pattern **1304** described by period p and contours of equal amplitude making an angle $\pi/2-\phi$ between a fixed but arbitrary vector \bar{X} perpendicular to surface normal \bar{n} . Standing-wave intensity-pattern **1304** may be produced by any of the interferometric or holographic methods well known to those practiced in the art. The apertures **1302** of aperture array mask **1301** so illuminated are simultaneously excited to the extent that the standing-wave mode-profile is congruent with the mode(s) guided by the individual apertures **1302**. The apertures **1302** are thereby excited to the extent that the antinodes of the standing-wave pattern overlap apertures **1302**.

Hence, the number and spacing of excited apertures may be further controlled to purpose either (i) by rotating mask **1301** and substrate **1303** together to effect a change in angle ϕ in support of the sixteenth advantage or (ii) by rotating standing-wave pattern **1304** about \vec{n} to effect a change in angle ϕ in support of the sixteenth advantage or (iii) by changing the period of the standing-wave pattern.

Referring to the drawings in detail, **FIG. 14A** and **FIG. 14B** illustrate, in schematic form, the presently preferred twelfth embodiment of the instant invention. The presently preferred twelfth embodiment can be understood as a simplification of the presently preferred sixth embodiment. Mask **1400** comprises a dielectric plate **1401**, with embedded dielectric cylinders **1402** and reflecting layer **1405**. It is understood that the type and arrangement of dielectric cylinders **1402** is not limited to the geometry of **FIG. 14A** and may be any instance described by any of the several preferred embodiments documented herein. Reflecting layer **1405** is advantageously placed on that mask surface which will be placed nearest the object-plane, as shown in **FIG. 14A**, wherein reflecting layer **1405** serves to improve the effective resolution of the aperture array by reflecting the evanescent component(s) of the guided mode(s) of a dielectric cylinder **1402**. The thickness of reflecting layer **1405** is therefore of the order of one or more times the skin-depth of light of the operating wavelength in the reflecting interlayer. A non-limiting example of a reflecting interlayer is a metal.

Reflecting layer **1405** may also be advantageously placed between dielectric layers near that mask surface which will be placed nearest the object-plane, as shown in **FIG. 14B**, where reflecting layer **1405** serves to improve the effective resolution of the aperture array by attenuating the evanescent component(s) of the guided mode(s) of a dielectric cylinder **1402**. The embodiment of **FIG. 14B** is advantageous over the embodiment of **FIG. 14A** inasmuch as the potential for interaction between the reflecting layer and materials in or near the object-plane is reduced in support of the tenth advantage. This is achieved by “burying” the reflecting layer **1405** behind a screening dielectric **1406**, which may or may not be identical in composition to dielectric plate **1401**. The criteria for choosing the thickness of reflecting layer **1405** are the same for the embodiment of **FIG. 14B** as for the embodiment of **FIG. 14A**.

Referring to the drawings in detail, **FIG. 15** illustrates, in schematic form, the presently preferred thirteenth embodiment of the instant invention. Mask structure **1500** may be any of the several presently preferred embodiments described elsewhere herein. The essential feature of mask **1500**, for the discussion of the presently preferred thirteenth embodiment, is the presence of dielectric cylinders **1502** possessing index of refraction n_3 .

Dielectric layer **1590** has the same index of refraction n_3 as dielectric cylinders **1502**. Dielectric layer **1590** thus facilitates matching of the transverse mode profile of an illuminating source to the guided modes concentrated in dielectric cylinders **1502**.

Antireflection structure **1591** is designed to minimize or eliminate reflection losses for light incident on the mask through antireflection structure **1591**. The particular symmetries of Maxwell's equations provide that the same structure simultaneously minimizes or eliminates reflection losses for light originating at the mask **1500** and conveyed through antireflection structure **1591**. Antireflection structure **1591** can be interpreted as an optical "impedance-matching" device ensuring maximal transfer of optical power from to and from the mask **1500**. The means to manufacture such antireflection structures **1591** are well known to those practiced in the art.

Any of the previously described embodiments of the mask may further include an end mask portion that provides with one or more sub-wavelength, secondary apertures at the end of each waveguide to further improve the spatial resolution of the source array. An aperture element for one such embodiment is shown schematically in **FIG. 16A**.

Source array mask **1610** includes a reflective dielectric stack **1620** and an end mask portion **1630** having an array of secondary apertures **1632**. Each mask aperture **1600** includes a waveguide **1622** formed by a dielectric material **1624** extending through dielectric stack **1620** and the secondary aperture **1632**. Moreover, in some embodiments the end mask portion may provide more than one secondary aperture for with each waveguide. As described above, dielectric stack **1620** may be formed by alternating layers (not shown) of dielectric material having refractive indices n_1 and n_2 . Furthermore, dielectric material **1624** forming waveguide **1622** may have a refractive index n_3 , such that $n_3 > n_1$ and $n_3 > n_2$. End mask portion **1630** may be formed by a metal layer, and secondary aperture **1632** may be selected to be a sub-wavelength aperture. In

other words, secondary aperture may have a transverse dimension smaller than that necessary to support a propagating mode in dielectric material **1624**.

In the embodiment shown in FIG. **16A**, end mask portion **1630** forms an interface with both dielectric stack **1620** and waveguide **1622**. In other embodiments, the end mask portion may form an interface primarily with waveguide **1622**, and have a limited lateral extent along reflective dielectric stack **1620**. One such embodiment is shown for source array mask **1660** in FIG. **16B**. Like mask **1610**, mask **1660** includes a reflective dielectric stack **1670** surrounding an array of apertures **1650**. Mask **1610** further includes an end mask portion **1680** having an array of secondary apertures **1682**. Each mask aperture **1650** includes a waveguide **1672** formed by a dielectric material **1674** extending through dielectric stack **1670** and secondary aperture **1682**. End mask portion **1680** extends along the width of each dielectric material **1624**.

Furthermore, to suppress multiple reflections between the object and the surface of mask **1660** nearest the object, mask **1660** may further include an anti-reflection layer **1690** formed on the surface of mask **1660** nearest the object. For example, the anti-reflection layer **1690** may surround end mask portion **1680** and waveguide **1682** as shown in FIG. **16B**. The anti-reflection layer **1690** may be formed by some combination of dielectric and/or metal layers. Moreover, mask **1660** may further include a metal layer **1665** sandwiched between dielectric stack **1670** and anti-reflection layer **1690** to minimize their interaction between.

One example of a suitable series of layers for the anti-reflection coating is as follows: a first 51 nm layer of silicon dioxide, a second layer 6 nm layer of Beryllium, a third 51 nm layer of silicon dioxide, followed by a fourth 50 nm layer of Aluminum on a silicon dioxide substrate, wherein the coating is designed to prevent reflections from an interface between the first layer and air.

Also, either of waveguides **1622** and **1672** in the respective masks may be designed to form a cavity between opposite sides of the mask. In such cases, the length of the waveguide is selected to cause the cavity to be resonant, or at least substantially resonant, at the wavelength of the radiation.
